Question What are the key features that distinguish common name reactions in organic synthesis? Key features include their well-documented mechanisms, specific reagents and conditions, predictable outcomes, and their historical significance in developing complex molecules. These reactions often have unique stepwise pathways that make them reliable tools for synthetic chemists. Can you explain the detailed mechanism of the Diels-Alder reaction? The Diels-Alder reaction proceeds via a concerted cycloaddition mechanism where a conjugated diene interacts with a dienophile. The pi electrons reorganize simultaneously to form two new sigma bonds, resulting in a six-membered ring. This pericyclic process involves a cyclic transition state governed by orbital symmetry considerations, often described by the Woodward-Hoffmann rules. What are some common variations in the mechanism of the Wittig reaction? The Wittig reaction mechanism involves formation of a phosphonium ylide, which then attacks the aldehyde or ketone carbonyl carbon to form a betaine intermediate. This intermediate then undergoes cyclization to form a four-membered

oxaphosphetane ring, which subsequently breaks down to give the alkene and a phosphine oxide. Variations can occur based on the nature of the ylide (stabilized vs. non-stabilized) and reaction conditions, affecting the stereoselectivity. How does the mechanism of the Mannich reaction proceed in detail? The Mannich reaction involves the formation of an iminium ion from an aldehyde or ketone reacting with formaldehyde or other aldehydes under acidic conditions. The enol or enolate form of the amine-reactant then nucleophilically attacks the iminium ion, leading to the formation of a β -amino carbonyl compound. The mechanism proceeds through proton transfers, stabilization of intermediates, and ultimately forms the Mannich base. What are the mechanistic steps involved in the Baeyer-Villiger oxidation? The Baeyer-Villiger oxidation involves the nucleophilic attack of a peracid (like mCPBA) on a ketone, forming a tetrahedral Criegee intermediate. This intermediate then rearranges, with migration of an alkyl or aryl group from carbon to oxygen, leading to the cleavage of the C-C bond and formation of an ester or lactone. The migration step is stereospecific and governed by migratory aptitudes of substituents.
